Large-scale simulations of spiking neural networks have become important tools in helping us improve the dynamics and, ultimately, the function of the brain. However, even small mammals such as mice have around 1×10^{12} synaptic connections (1), the strengths of which are typically modelled as individual floating point values. If single precision floating point were used to store these values, several terabytes of memory would be required. As such memory requirements are beyond what is plausible for a single machine, simulations of large-scale spiking neural network currently are typically simulated on large distributed systems. Large parts of such models are typically described by simple algorithms which describe connectivity and the strength of synaptic connections. In this work, we describe our extensions to GeNN (2) - our GPU-based spiking neural network simulator - to enable it to 'procedurally' generate connectivity and synaptic weights as spikes are received rather than retrieving them in memory. We find that high-end GPUs are well-suited to this approach as they provide a large amount of raw computational power which is often under-utilised when simulating spiking neural networks due to the limited memory bandwidth available to each parallel computing element. To demonstrate the value of this approach, we present the results of simulations of a recent model of the Macaque visual cortex consisting of 4.13×10^6 neurons and 24.2×10^9 synapses on a single GPU and show that the results are correct and the simulation runs faster than previous simulations which ran on over 1000 supercomputer nodes.

spiking neural networks | GPU | high-performance computing | brain simulation

While the brain of a mouse has around 70×10^6 neurons, their numbers are dwarved by the 1×10^{12} synapses which connect them. Computationally, simulating spikes propagating through synapses involves reading a 'row' of synapses connecting a spiking presynaptic neuron to its postsynaptic partners and adding the 'weight' of each synapse in the row to a 'bin' containing the postsynatic neuron's input for a simulation timestep.

Because of the high memory requirements of large-scale brain models, they are typically simulated on large distributed systems using software such as NEST (3) or NEURON (4). By careful design, such simulators can maintain a constant memory requirements for each node can kept constant even when a simulation is distributed across thousands of nodes (5). However, such systems are large, expensive and consume large amounts of power meaning that they are typically shared between many researchers from many institutions.

Neuromorphic systems (6–11) take inspiration from the brain and have been developed specifically for simulating spiking neural networks. One particular relevant feature of the brain is that its memory elements – the synapses – are located throughout the system rather than being centrally located. In neuromorphic systems, this often translates to

a large proportion of each chip being dedicated to memory. However, while such on-chip memory is fast, it can only be fabricated at relatively low density meaning that many of these systems economize – either by reducing the maximum number of synapses per neuron to as few as 256 or by reducing the precision of the synaptic weights to 6 (11), 4 (6) or even 1 bit (7, 9). While such strategies allow some classes of spiking neural networks to be simulated very efficiently, in the context of large-scale brain simulation, reducing the degree of connectivity to fit within the constraints of such a system inevitably changes its dynamics (12). Unlike the majority of other other neuromorphic systems, SpiNNaker (8) is entirely programmable and combines a large amount of on-chip meory with external memories, distributed across the system for the storage of synaptic connectivity. SpiNNaker's external memory bandwidth, on-chip memory capacity and the computational power of each core are all tailored to large-scale brain simulation meaning that the output bins of the synapse processing algorithm can fit in on-chip memory and there is enough external memory bandwidth to fetch synaptic rows fast enough for real-time simulation of large-scale models (13). (TODO: good argument against SpiNNaker)

GPU architectures have relatively small amounts of on-chip memory and, instead, dedicate the majority of their silicon area to arithmetic logic units (ALUs). GPUs use dedictated hardware to rapidly switch between tasks meaning that, as long as there is sufficient computation to be performed, the latency of accessing external memory can be 'hidden' behind computation. For example, each CUDA core of a modern GPU needs to perform approximately 10 arithmetic operations per byte of data accessed from memory in order to successfully hide the memory latency. However, processing a synapse is likely to require accessing approximately 8 B of memory and performing many fewer than 80 instructions, making this operating highly

Significance Statement

Authors must submit a 120-word maximum statement about the significance of their research paper written at a level understandable to an undergraduate educated scientist outside their field of speciality. The primary goal of the Significance Statement is to explain the relevance of the work in broad context to a broad readership. The Significance Statement appears in the paper itself and is required for all research papers.

J.K. and T.N. wrote the paper. T.N. is the original developer of GeNN. J.K. is currently the primary GeNN developer and was responsible for extending the code generation approach to the procedural simulation of synaptic connectivity. J.K. performed the experiments and the analysis of the results that are presented in this work.

The authors declare no conflict of interest.

memory bound. Nonetheless, in our previous work (14) we showed that, as GPUs have significantly higher total memory bandwidth than even the most expensive CPU, moderately sized models of around 10×10^3 neurons and 1×10^9 synapses can be simulated on a single GPU with competitive speed and energy requirements. Nonetheless, individual GPUs do not have enough memory to simulate truly large-scale brain models and, although small numbers of GPUs can be connected together using the high-speed NVLink (TODO: cite) interconnect, beyond this scaling will be dictated by the same communication overheads as other distributed systems.

In this work we present an approach which converts large-scale brain simulation from a problem which is memory-bound on a GPU to one where the large amount of computational power available on a GPU can be used to reduce the memory and memory bandwidth requirements and make large-scale brain simulations on a single workstation possible.

Results

In the following subsections we will first present two novel features of our GeNN simulator (2) which allow it be used for simulating large-scale models on a single GPU. Finally, we will demonstrate the power of both features by simulating a recent model of the Macaque visual cortex (15) consisting of 4.13×10^6 neurons and 24.2×10^9 synapses on a single GPU and demonstratint that, not only are the results correct, but the simulation runs faster than simulations previously run on a supercomputer system.

Procedural connectivity. Our GeNN simulator (2) uses code generation to convert neuron and synapse models – described using 'snippets' of C-like code – into CUDA code for GPU simulation. We previously extended GeNN to allow the same approach to be applied to generating efficient, parallel model initialisation code from code snippets describing the algorithms to use for initialising individual state variables and synaptic connectivity (14). Parallelising initialisation in this manner sped up model initialisation by around 20× on a desktop PC, but also indicates just how well-suited these initialisation algorithms are to GPU. In fact, it seems somewhat illogical to run these algorithms once only to fill the limited memory of the GPU with data and subsequently read it back throughout

the simulation

To demonstrate the performance and scalability of this new approach, we ran several simulations of a network, initially designed as a medium for experimentation into signal propagation through cortical networks (16), but subsequently widely used as a scalable benchmark (17). The network consists of 10 000 integrate-and-fire neurons, split between an excitatory population of 8000 cells and an inhibitory population of 2000 cells.

Kernel merging. While the procedural connectivity approach presented in the previous section allows us to simulate models which would otherwise not fit within the memory of a single GPU, there are additional problems when using code generation to generate simulation code for models with large numbers of neuron and synapse populations.

The multi-area model. Due to lack of computing power and sufficiently detailed connectivity data, previous models of the cortex have either focussed on modelling individual local microcircuits (18, 19) at the level of individual cells or modelling multiple connected areas at a higher level of abstraction where entire ensembles of neurons are described by a small number of differential equations (TODO: find citation). However, data from several species (TODO: find citation) has shown that cortical activity has distinct features at both the global and local levels which can be captured by modelling interconnected microcircuits at the level of individual cells.

By using a supercomputer to simulate a model based on the latest connectivity data and The multi-scale model of the macaque visual cortex (15) developed by

Discussion

- Further scaling memory only required for neuron parameters
- Learning
- Hardware for procedural connectivity?

Materials and Methods

Please describe your materials and methods here. This can be more than one paragraph, and may contain subsections and equations

- as required. Authors should include a statement in the methods 135 section describing how readers will be able to access the data in the paper. 137
 - LIF neuron
